카드 요약 / 당시 확인 내용

A study published in August 2026 found that glyphosate reduces honeybee foraging activity by 13% following just three days of exposure, while altering neurochemical profiles associated with navigation and learning. The findings challenge the assumption that glyphosate poses no risk to pollinators because bees lack the enzyme the herbicide targets in weeds. The chemical does not kill bees directly, but exposed bees showed measurable changes in brain chemicals linked to spatial orientation and behavior essential for efficient foraging. A 13% foraging reduction across commercial hives compounds existing pressures including varroa mites, habitat loss and neonicotinoid pesticides; honeybee pollination supports approximately \$15 billion in annual U.S. agricultural output. The findings emerge as Bayer consolidates its \$2.4 billion U.S. glyphosate operations into Ruveon and as European regulatory scrutiny intensifies, reinforcing interest in precision application such as variable-rate spraying and drones.
